## Precise determination of the fine structure constant and test of quantum electrodynamics

Wednesday, 17 September 2014 08:30 (30 minutes)

In our experiment the fine structure constant is deduced from the measurement of the recoil velocity of an atom when it absorbs a photon. Such a measurement is performed by combining a Ramsey-Bord\'e atom interferometer with Bloch oscillations. We obtain a value of  $\alpha$  with a relative uncertainty of  $6.6 \times 10^{-10}$ \cite{Bouchendira}. Using this value of  $\alpha$ , we obtain a theoretical value of the electron magnetic moment in agreement with the experimental measurement of

Harvard's group. The comparison of these values provides the most stringent test of QED. Moreover, the uncertainty is small enough

to verify for the first time the muonic and hadronic contributions

to the electron magnetic moment.

In this talk we will discuss the latest developments of this experiment.
